Copy Fail (CVE-2026-31431) - C port

(English (en)) · 日本語 (ja) · 简体中文 (zh-cn) · 한국어 (ko) · Русский (ru)

A cross-platform C reimplementation of the Copy Fail Linux LPE (CVE-2026-31431), disclosed 2026-04-29 by Theori / Xint. See the canonical writeup at copy.fail for the full vulnerability description, timeline, and Theori's discovery process.

The publicly-released proof-of-concept is a 732-byte Python script. This C port demonstrates that the same exploit can be expressed as portable C: compilable for any architecture nolibc supports, with no per-arch hex blobs or inline assembly in the project's own source.

Author of this port: Tony Gies tony.gies@rashunited.com. Discovery and original disclosure: Theori / Xint.

└── vulnerable             non-destructive vulnerab
```

`exploit.c` opens the target binary read-only, then for each 4-byte window of the embedded payload runs one bogus AEAD-decrypt through AF_ALG whose ciphertext input is supplied via splice() from the target's page-cache pages. The authencesn template's in-place optimization treats the spliced'd source pages as both the ciphertext input and the plaintext destination, so the (failing) decrypt has already overwritten the page-cache page by the time the authentication verification rejects the request. After 4 * N iterations the target's cached image has been replaced byte-for-byte with the payload. execve()ing the target loads the mutated pages; the on-disk inode is still setuid root, so the kernel grants root credentials and runs `/usr/bin/su`.

`payload.c` is plain portable C: `setgid(0); setuid(0); execve("/bin/sh", ...)`. nolibc supplies the `_start` , the syscall machinery, and the per-arch register-juggling.

A second variant, `exploit-passwd.c` , mutates four bytes of /etc/passwd's page cache instead of a setuid binary's image. It needs no embedded payload and works on systems where the binary-mutation route is blocked, but its cashout surface is much narrower.

`vulnerable.c` is not an exploit. It creates a local `testfile` containing the string `init` , then runs the same `patch_chunk()` primitive against that file's own page cache to overwrite the bytes with `vulnerable` . If the read-back contents match, the running kernel is in-window for CVE-2026-31431. The on-disk inode is never modified; `testfile` is removed on exit; the page-cache mutation evaporates with it. Runs unprivileged. Exits 100 if vulnerable, 0 if the primitive ran but the mutation did not take, 2 if the AF_ALG socket family or authencesn template is unavailable so patch state cannot be determined, and 1 for runtime errors.

Build

Default (host-arch native):

```
make
```

Cross-compile to aarch64 (or any other Linux arch a cross-toolchain is installed for):

```
make CC=aarch64-linux-gnu-gcc LD=aarch64-linux-g
```

Architectures supported by the vendored nolibc (per upstream): x86_64, i386, arm, aarch64, riscv32/64, mips, ppc, s390x, loongarch, m68k, sh, sparc. `nolibc` dispatches on the compiler's `__x86_64__` macros, so picking the right `CC` / `LD` is sufficient.

Required to build:

- a C compiler (`cc` , `gcc` , or any cross variant)
- a linker that supports `ld -r -b binary` (binutils ld and lld both do)
- kernel UAPI headers providing `linux/if_alg.h` and `<asm/unistd.h>` (Debian/Ubuntu: `linux-libc-dev` ; cross variants: typically pulled in by the cross-toolchain package)

There are no external library dependencies. The payload is built freestanding against nolibc; the dropper links against the host libc only for `fprintf` and `perror` .

Architectural choices

Three small toolchain features carry most of the weight in keeping the source portable and the payload small.

nolibc

`nolibc/` is the kernel's tiny header-only libc replacement, vendored from torvalds/linux `tools/include/nolibc/` . It provides `_start` , a portable `syscall()` macro, and inline syscall wrappers, with the per-arch register conventions encoded in `nolibc/arch-*.h` . Building the payload with `-nostdlib -static -ffreestanding -lnolibc` produces a tiny static ELF that calls into the kernel directly without dragging in glibc startup, TLS init, or stack-canary plumbing. Result: ~1.7 KB on x86_64, ~2.0 KB on aarch64, versus ~17 KB for the same `payload.c` linked against musl-static or ~700 KB against glibc-static.

`ld -r -b binary` for embedding

The Makefile turns the built `payload` ELF into `payload.o` via `ld -r -b binary -o payload.o payload` . The linker emits the input bytes verbatim as the data section of a relocatable object file and synthesizes three symbols from the input filename:

```
_binary_payload_start    address of first payloa
_binary_payload_end      address one past the la
_binary_payload_size     absolute symbol whose v
```

`exploit.c` declares the first two as `extern const unsigned char[]` and computes the size as `_binary_payload_end - _binary_payload_start` .

`-Wl,-N` plus tight `max-page-size`

`-Wl,-N -Wl,-z,max-page-size=0x10` , which collapses `.text` / `.rodata` / `.data` into a single LOAD segment with 16-byte file-alignment instead of the kernel-page-aligned 4 KB per-segment default. This produces an "RWX permissions" warning from `ld` , which is informational only - the payload's runtime memory protection doesn't matter to its single-purpose program. Without this flag, the same code links to ~13 KB on x86_64 (mostly inter-segment zero padding); with it, ~1.7 KB.

Variants and cashout viability

This repository ships two exploit variants that share the AF_ALG/splice page-cache mutation primitive but cash out into root execution differently. Their reliability profiles are not equivalent, and the difference matters when reasoning about real-world threat models.

Binary-mutation variant (`exploit`)

Mutates the page cache of a target setuid binary with the embedded payload bytes, then execs the binary. The kernel grants root credentials from the binary's untouched on-disk setuid bit, loads the corrupted in-memory image, and runs the payload.

Works wherever the attacker can `open(target, O_RDONLY)` for any root-setuid binary on the system. More or less defeated by environments that gate setuid binaries behind restricted-read directories and by setuid-free system designs.

/etc/passwd UID-flip variant (`exploit-passwd`)

Mutates four bytes of /etc/passwd's page cache to set the running user's UID field to "0000". /etc/passwd is world-readable on every standard Linux system, so the *mutation* is universal. Translating it into root execution depends on some root-side process resolving the user via getpwnam/getpwuid and acting on the resolved uid without cross-validation. Many such consumers exist; many of them defensively cross-check against the file's view of the calling uid or against on-disk ownership, breaking the cashout.

Cashout viability matrix

Cashout	Pre-root setup needed	Notes
WSL2 session spawn	No	WSL's per-session `setuid(getpwnam(default_uid))` does no validat Works cleanly.
util-linux `su`	No	Permissive caller-identity handling.
shadow-utils `su`	Yes	`getpwuid(getuid())` calls identity check fails becau mutation unmaps the rea

Pivoting after `su` fails

`exploit-passwd` execs `su <user>` after mutating, as the simplest possible cashout. That works against util-linux `su` but fails against shadow-utils `su` with "Cannot determine your user name." The page cache mutation is still in place at that point, and pivoting to any other cashout (e.g. using a daemon resolving users via getpwnam without cross-checking) is possible at that point. Run `echo 3 > /proc/sys/vm/drop_caches` as root to clear the corrupted page cache when done testing.

Affected kernels

In between: every major distro kernel that didn't backport the fix. Ubuntu, RHEL, SUSE, Amazon Linux, and Debian were all confirmed vulnerable in their stock cloud-image kernels at disclosure time. Distro-level backports started rolling out around 2026-04-29 alongside the public disclosure. To verify whether a target kernel is in-window, check whether `a664bf3d603d` (or its distro-specific backport) is present in the kernel's git log or the distro's changelog.
